**Summary** This study examined how leaf and stem functional traits related to gas exchange and water balance scale with two potential proxies for tree hydraulic architecture: the leaf area:sapwood area ratio ( $A_L:A_S$ ) and wood density ( $\rho_w$ ). We studied the upper crowns of individuals of 15 tropical forest tree species at two sites in Panama with contrasting moisture regimes and forest types. Transpiration and maximum photosynthetic electron transport rate ( $ETR_{max}$ ) per unit leaf area declined sharply with increasing  $A_L:A_S$ , as did the ratio of  $ETR_{max}$  to leaf N content, an index of photosynthetic nitrogen-use efficiency. Midday leaf water potential, bulk leaf osmotic potential at zero turgor, branch xylem specific conductivity, leaf-specific conductivity and stem and leaf capacitance all declined with increasing  $\rho_w$ . At the branch scale,  $A_L:A_S$  and total leaf N content per unit sapwood area increased with  $\rho_w$ , resulting in a 30% increase in  $ETR_{max}$  per unit sapwood area with a doubling of  $\rho_w$ . These compensatory adjustments in  $A_L:A_S$ , N allocation and potential photosynthetic capacity at the branch level were insufficient to completely offset the increased carbon costs of producing denser wood, and exacerbated the negative impact of increasing  $\rho_w$  on branch hydraulics and leaf water status. The suite of tree functional and architectural traits studied appeared to be constrained by the hydraulic and mechanical consequences of variation in  $\rho_w$ .

**Keywords:** capacitance, functional convergence, hydraulic architecture, osmotic potential, photosynthesis, transpiration, water potential.

### Introduction

Because the integrity and efficiency of long-distance water transport are critical to the growth and survival of land plants, especially trees, fundamental features constraining hydraulic architecture are expected to play a dominant role in determin-

ing a broad range of functional traits. Whole-plant leaf area-specific conductance ( $K_l$ ) is a higher order component of hydraulic architecture that integrates the hydraulic properties of the entire soil-to-leaf water transport pathway (Küppers 1984). As an index of the efficiency of water supply in relation to potential transpirational demand,  $K_l$  is expected to constrain stomatal control of leaf gas exchange and water balance (Meinzer 2002, Sperry et al. 2002), and a number of studies have reported a close coordination between  $K_l$  and leaf gas exchange both within (Meinzer and Grantz 1990, Hubbard et al. 2001) and across (Meinzer et al. 1995, Mencuccini 2003, Santiago et al. 2004, Campanello et al. 2008) species. Similarly, the leaf area to sapwood area ratio ( $A_L:A_S$ ) is a tree architectural index of potential transpirational demand relative to water transport capacity and therefore a potential proxy for  $K_l$  (Andrade et al. 1998, Tausend et al. 2000, Bucci et al. 2005).

In diffuse-porous species, variation in wood density ( $\rho_w$ ) should constrain stem hydraulics (Stratton et al. 2000) because  $\rho_w$  is an index of the balance between solid material and the relative cross-sectional area available for water transport. Plant functional traits shown to be inversely related to  $\rho_w$  include rates of leaf gas exchange (Bucci et al. 2004, Santiago et al. 2004), xylem-specific and leaf-specific conductivity (Stratton et al. 2000, Bucci et al. 2004, Santiago et al. 2004), minimum leaf water potential (Bucci et al. 2004, Santiago et al. 2004), leaf osmotic potential at the turgor loss point (Gartner and Meinzer 2005), xylem vulnerability to embolism and implosion (Hacke et al. 2001) and xylem hydraulic capacitance (Meinzer et al. 2003, Pratt et al. 2007, Scholz et al. 2007).

Because multi-species surveys involving measurement of hydraulics in intact, field-grown plants present a series of methodological and logistical difficulties associated with simultaneous measurements of water fluxes and their driving forces, both of which are rarely steady state (Goldstein et al. 1998, Andrade et al. 1998, Domeq et al. 2007), the ability to

link higher order functional traits to tree architectural features and biophysical properties that are relatively simple to measure would be beneficial. Nevertheless, relatively few studies have examined the extent to which higher order functional traits and physiological regulatory behavior scale in a species-independent manner with basic structural and biophysical attributes that govern hydraulic architecture. Correlations among traits may not necessarily be indicative of the mechanisms driving the relationships, but comparisons of multiple relationships across a range of organization from the simplest physical traits to more complex functional traits are likely to suggest potential mechanisms underlying the scaling relationships observed.

We studied individuals of 15 tropical forest tree species at two sites in Panama with contrasting rainfall regimes and forest types to examine how a number of leaf, stem and branch level functional traits related primarily to gas exchange and water balance scale with  $A_L:A_S$  and  $\rho_w$  of upper canopy branches. For the reasons outlined above,  $A_L:A_S$  and  $\rho_w$  are potential surrogates for various aspects of tree hydraulic architecture that should provide a basis for drawing inferences concerning the mechanistic nature of the leaf- and branch-level scaling relationships observed. We hypothesized that scaling relationships would be driven by the impacts of variation in  $A_L:A_S$  and  $\rho_w$  on hydraulic architecture and water balance. Specifically, we expected to observe inverse relationships between  $A_L:A_S$  and indices of leaf gas exchange capacity because  $A_L:A_S$  is a potential architectural proxy for  $K_L$ . As such, increasing  $A_L:A_S$  would imply decreasing water supply in relation to demand. In addition, we predicted that xylem specific conductivity and hydraulic capacitance would be inversely related to  $\rho_w$  and that these inverse relationships would be associated with greater fluctuations in leaf water status in species with denser wood.

## Materials and methods

### Study sites and plant material

Data were collected during the dry seasons of 1994, 1996, 2000, 2001, 2003 and 2004 from two canopy cranes operated by the Smithsonian Tropical Research Institute (STRI) in the Republic of Panama. Each crane is equipped with a gondola suspended by cables from a rotating jib that allows access to about 0.8 ha of forest. One crane is located in an old-growth forest in the Parque Nacional San Lorenzo on the Caribbean side of the Isthmus of Panama, where mean annual precipitation is about 3100 mm. The other crane is located in a seasonally dry secondary forest in the Parque Natural Metropolitano near the edge of Panama City, which receives about 1800 mm of precipitation annually, with a distinct dry season between late December and April. The dry season at Parque San Lorenzo is shorter and less intense than at Parque Metropolitano. There is no overlap among tree species between the two sites. Seven individuals were studied at the Parque San Lorenzo site and eight at the Parque Metropolitano site representing a total of 15 species (Table 1).

### Transpiration

The constant heating method described by Granier (1985) was used to measure transpiration ( $E$ ) as sap flow through branches in the upper crowns of 12 species. For measurements in 1996, a pair of 20-mm-long, 2-mm-diameter temperature probes (UP GmbH, Munich, Germany) was installed in each of three to four replicate branches per tree. The upper (downstream) probe was continuously heated with a constant current power supply (UP GmbH), while the unheated upstream probe served as a temperature reference. For measurements in 2000, 2001 and 2004, variable length probes with a heated and

reference sensor measuring length of 10 mm at the probe tip (James et al. 2002) were installed in three to five replicate branches per tree. All probes were shielded with a layer of foam insulation surrounded by an outer layer of reflective insulation. Concurrent differential voltage measurements across the copper thermocouple leads were converted to a temperature difference between the heated and reference sensor ( $\Delta T$ ). Signals from the sap flow probes were scanned every minute and 10-min means were recorded by a data logger equipped with a 32-channel multiplexer and stored in a solid-state storage module. Mass flow of sap was obtained by multiplying flow density by the sapwood area, which included the entire cross-sectional area of the xylem for the size range of branches in which probes were installed (3 to 6-cm-diameter). Leaf area distal to the probes ranged from 2 to 13 m<sup>2</sup> and was determined by multiplying the total number of leaves by the mean area per leaf obtained from a subsample of 50 to 200 leaves.

#### Photosynthetic capacity and leaf nitrogen content

Chlorophyll fluorescence was measured on 10 species during 2003 using a pulse-amplitude modulated yield analyzer (Mini-PAM, Waltz, Effeltrich, Germany). Saturation pulses were applied for 0.8 s at a photosynthetic photon flux (PPF) of 3500  $\mu\text{mol m}^{-2} \text{s}^{-1}$ . Measurements were made between predawn and midday in fully expanded and exposed sun leaves to minimize the impacts of any afternoon depression in photosynthetic capacity or photoinhibition associated with acclimation to shade. Quantum yields of PS II were obtained for the complete range of PPF values experienced by plants (0 to 2000  $\mu\text{mol m}^{-2} \text{s}^{-1}$ ). Measurements of PPF were made with the Mini-PAM's micro-quantum sensor. A steady-state light response curve for each species was generated with leaves adapted to the PPF values measured in the field. Maximum fluorescence yield ( $F_m$ ) and dark fluorescence yield ( $F_o$ ) of PSII were recorded in predawn conditions to determine dark-adapted quantum yields ( $F_o/F_m = F_m - F_o/F_m$ ). Dark-adapted quantum yield corresponded to the initial points of the light curves. Steady-state fluorescence ( $F$ ) and maximal fluorescence in the light-adapted state ( $F_m'$ ) of PSII were measured for different PPF values. Values of electron transport rates (ETR) through PSII were obtained from quantum yield ( $\Delta F/F_m' = (F_m' - F)/F_m'$ ):

$$\text{ETR} = (\Delta F/F_m') I \alpha 0.5 \quad (1)$$

where  $I$  is the incident PPF, and  $\alpha$  is leaf absorbance. The 0.5 factor assumes an even distribution of absorbed quanta between PSII and PSI so two photons are required per electron passed through PSII. The ETR correction factor " $\alpha$ " takes into account that only a fraction of incident light is absorbed by the two photosystems. A value of  $\alpha = 0.84$  was used for calculations (Ehleringer 1981, Björkman and Demmig 1987).

The photosynthetic capacity expressed as the maximum electron transport rate ( $\text{ETR}_{\text{max}}$ ;  $\mu\text{mol electrons m}^{-2} \text{s}^{-1}$ ) was calculated from light curves using the asymptotic exponential equation:

$$y = (\text{ETR}_{\text{max}}) (1 - e^{-bx}) \quad (2)$$

where  $y$  is photosynthetic rate,  $x$  is irradiance and  $b$  is the instantaneous fractional growth rate of the exponential function (Rascher et al. 2000). Curve fits obtained with this equation yielded  $r^2$  values ranging from 0.87 to 0.99, consistent with the absence of significant photoinhibition.

Foliage on which chlorophyll fluorescence was measured was collected, dried and ground and analyzed for N content on a Carlo Erba elemental analyzer (NC 2500, CE Elantech, Lakewood, NJ). For the remaining five species, total N content of fully exposed upper canopy leaves was determined by the micro-Kjeldahl method. Leaf mass per area (LMA) was determined on a minimum of five leaves per species.

#### Leaf water relations

The water potential of upper-canopy leaves ( $\Psi_L$ ) of nine species was determined with a pressure chamber (PMS Instrument Company, Albany, OR) near midday on clear dry days during the dry season. At each sampling time, measurements were obtained from three to five leaves of each tree. Balance pressures were determined either in the canopy crane gondola immediately after leaf excision, or the leaves were sealed in plastic bags and dropped to the base of the crane for determination of balance pressures within 10 min of excision.

The pressure–volume technique (Tyree and Hammel 1972) was used to assess bulk leaf osmotic potential at zero turgor ( $\Psi_{\pi z}$ ) and leaf capacitance ( $C$ ) in nine of the species. Portions of terminal branches were excised in the upper canopy and their bases immediately recut under water. The cut ends remained under water with the terminal leafy portions enclosed in a plastic bag to allow partial rehydration during transit from the canopy crane to the laboratory. Individual leaves or leafy shoots were used for pressure–volume analyses depending on petiole length and leaf size. Pressure–volume curves were initiated by first determining the fresh mass of the sample, then measuring its water potential with a pressure chamber. Alternate measurements of fresh mass and  $\Psi_L$  were repeated during slow dehydration on the laboratory bench until  $\Psi_L$  approached the measuring range of the pressure chamber ( $-4$  MPa). We tested for rehydration-induced artifacts previously reported for some woody species (Bowman and Roberts 1985, Meinzer et al. 1986, Evans et al. 1990) by comparing pressure–volume curves obtained from samples at different levels of initial hydration and found none. The transition point between the nonlinear and linear portions of the curve was taken to be the bulk tissue osmotic potential at zero turgor. Bulk leaf  $C$  was determined from the slope of the relationship between relative water content and  $\Psi_L$  obtained from pressure–volume curves at values of  $\Psi_L$  less negative than  $\Psi_{\pi z}$ . Values of osmotic potential and  $C$  reported here are means from three to five curves per species.

#### Stem water relations

Moisture release curves for sapwood of terminal branches were determined for ten species according to the method de-

scribed by Meinzer et al. (2003). Briefly, small cylinders of sapwood were allowed to hydrate in distilled water overnight and then quickly blotted to remove excess water, placed in the caps of thermocouple psychrometer chambers (83 Series, JRD Merrill Specialty Equipment, Logan, UT), weighed, and sealed inside the rest of the chamber for determination of  $\Psi$  isotherms. Each chamber contained three cylindrical tissue samples. The psychrometer chambers were placed in an insulated water bath and allowed to equilibrate for 2 to 3 h before measurements were started with a 12-channel digital psychrometer meter (85 Series, JRD Merrill Specialty Equipment). Measurements were repeated at 30-min intervals until the  $\Psi$  values stabilized. The chambers were opened and the samples were allowed to dehydrate for different time intervals, reweighed in the psychrometer caps, resealed inside the psychrometer chambers and allowed to equilibrate for another determination of  $\Psi$ . Moisture release curves were generated by plotting sapwood  $\Psi$  against relative water deficit. Data points from three to four replicate curves per species were pooled. Species-specific values of sapwood  $C$  ( $\text{kg m}^{-3} \text{MPa}^{-1}$ ) were taken as the slopes of linear regressions fitted to the initial phase of moisture release curves plotted as the cumulative mass of water released against sapwood  $\Psi$  (Meinzer et al. 2003). Mass of water per unit sapwood volume at saturation ( $\text{kg m}^{-3}$ ) was calculated by multiplying the saturated/dry mass ratio by sapwood density ( $\text{kg m}^{-3}$ ) and subtracting sapwood density. The cumulative mass of water released per unit sapwood volume was then calculated by multiplying the tissue relative water deficit at a given value of sapwood  $\Psi$  by the mass of water per unit sapwood volume at saturation. Density was determined for small cylinders of sapwood collected as described above. Volume displacement was determined for samples of saturated tissue, which were oven dried for determination of mass.

Maximum specific conductivity ( $k_s$ ) was determined for segments of terminal branches 2–5 cm in diameter and greater than 35 cm in length excised near the top of the canopy. After excision, the branches were immediately recut under water in the crane gondola and transported to the laboratory for measurement. In the laboratory, a 15 to 17-cm-long section of each branch (0.7 to 1.2 cm in diameter) was cut and both ends were smoothed with clean razor blades. The stem segments were then sealed into a double-ended pressure chamber with both ends protruding and attached with tubing to an apparatus for measuring hydraulic conductivity ( $k_h$ ). The downstream end of the segment was connected to a 1-ml graduated pipette and the upstream end of the segment was attached to tubing connected to a reservoir of filtered water (0.22  $\mu\text{m}$ ) that was pressurized at 0.15 MPa for 40 min to remove emboli and restore the segment to its maximum conductivity. The pressure was then lowered to 5.5 kPa and the chamber was pressurized to 0.05 MPa to prevent extrusion of water from leaf scars during measurement of axial flow. When flow had stabilized, the time required for the meniscus in the pipette to cross five consecutive graduation marks (0.5 ml) was recorded. Maximum  $k_h$  was calculated as the mass flow rate through the segment divided by the pressure gradient ( $\text{MPa m}^{-1}$ ) across the segment. Conduc-

tivity was divided by the xylem cross-sectional area to obtain  $k_s$  and by the leaf area distal to the segment to obtain leaf-specific conductivity ( $k_l$ ). Conductivity data reported here are means of values obtained from five to six stem segments per species. Following conductivity measurements, xylem density was determined as described above.

The water potential of terminal branches ( $\Psi_{br}$ ) was estimated with a pressure chamber from balance pressures of covered, non-transpiring leaves (Meinzer et al. 2003). Leaves were enclosed in aluminum foil and plastic bags in the afternoon before the day of measurements. At each sampling time, measurements were obtained from three to five leaves of each tree as described above for exposed leaves.

### Statistical analysis

Trends in sapwood area-based  $\text{ETR}_{\text{max}}$  and  $E$  with  $\rho_w$  (Figure 5b) were modeled by first using the regression fitted to the relationship between  $A_L:A_S$  and  $\rho_w$  ( $y = 1.60x - 0.18$ ; Figure 5a). The corresponding values of  $A_L:A_S$  were then used in the regression equations developed for the data in Figures 1 and 2a to obtain values of  $E$  ( $y = 0.42 + 36.54e^{(-8.96x)}$ ) and  $\text{ETR}_{\text{max}}$  ( $\log(y) = 1.95 - 0.78\log(x)$ ), which were multiplied by  $A_L:A_S$  to convert from a unit leaf area basis to a branch sapwood area basis. These estimates were then normalized to values at a  $\rho_w$  of 0.3  $\text{g cm}^{-3}$ , which corresponded roughly to the lowest  $\rho_w$  among the species studied. Pearson correlations were used to analyze relationships between functional traits and  $A_L:A_S$  or  $\rho_w$  after log transformation of data. Significance levels of least squares regressions were assessed by ANOVA. Differences in  $A_L:A_S$  and  $\rho_w$  among sites were evaluated by one-way ANOVA with site as the main factor. Differences in the dependence of sapwood  $C$  on  $\rho_w$  among sites were assessed by one-way ANCOVA after confirming homogeneity of the regressions for the two sites ( $F = 0.64$ ,  $P = 0.45$ ).

### Results

Values of branch  $A_L:A_S$  and  $\rho_w$  varied widely among the 15 trees studied (Table 1). Branch  $A_L:A_S$  was higher at the wetter San Lorenzo site than at the drier and more seasonal Parque Metropolitano ( $P = 0.04$ ). Mean  $\rho_w$  was also significantly greater ( $P = 0.004$ ) for the trees studied at the Parque San Lorenzo site. Mean basal diameter and height of the trees selected for study were similar across the two sites. Nine of the 12 leaf and stem functional traits examined were significantly correlated with  $A_L:A_S$  or  $\rho_w$  across species (Table 2).

Several scaling relationships of leaf functional traits with tree architecture and  $\rho_w$  were identified. Transpiration per unit leaf area declined sharply with increasing  $A_L:A_S$  for the 12 species in which upper-branch sap flow was measured as a proxy for transpiration (Figure 1). Consistent with the behavior of transpiration,  $\text{ETR}_{\text{max}}$ , an index of photosynthetic capacity, and the ratio of  $\text{ETR}_{\text{max}}$  to leaf N content ( $\text{ETR}_{\text{max}}/N$ ), an index of instantaneous photosynthetic nitrogen-use efficiency, also declined with increasing  $A_L:A_S$  ( $P < 0.0001$  and  $P = 0.003$ , respectively; Figure 2). The inverse relationship between  $\text{ETR}_{\text{max}}/N$  and  $A_L:A_S$  was not associated with significant trends

in leaf N content on a mass or area basis with variation in  $A_L:A_S$  or  $\rho_w$  (Table 2 and data not shown).

Both midday leaf water potential ( $\Psi_L$ ) and the bulk leaf osmotic potential at zero turgor ( $\Psi_{\pi z}$ ) declined linearly with increasing  $\rho_w$  ( $P = 0.0003$  and  $0.004$ , respectively, Figure 3a). Variation in  $\rho_w$  explained about 84% of the variation in  $\Psi_L$ . The slopes of the regression lines were not statistically different, implying that minimum values of bulk leaf turgor were similar across species when the daily minimum value of  $\Psi_L$

Figure 1. Maximum branch transpiration rate per unit leaf area ( $E$ ) in relation to leaf area:sapwood area ratio ( $A_L:A_S$ ) for upper crown branches of 12 Panamanian forest tree species growing in two sites with different rainfall regimes and forest types. Values are means of three to five branches per tree. Open symbols, drier site; closed symbols wetter site.

was attained. The specific conductivity of branch sapwood ( $k_s$ ) decreased exponentially from a maximum value of about  $12 \text{ kg m}^{-1} \text{ s}^{-1} \text{ MPa}^{-1}$  when branch  $\rho_w$  was  $0.4 \text{ g cm}^{-3}$  to a minimum value of  $1.6 \text{ kg m}^{-1} \text{ s}^{-1} \text{ MPa}^{-1}$  when  $\rho_w$  was  $0.74 \text{ g cm}^{-3}$  (Figure 3b). Species from both sites appeared to share a common relationship between  $k_s$  and  $\rho_w$ . However,  $k_s$  was not significantly correlated with  $A_L:A_S$  (Table 2). Consistent with the relationship between  $k_s$  and  $\rho_w$ ,  $k_l$  decreased exponentially with  $\rho_w$  (Figure 3c). Sapwood  $C$  also declined sharply with increasing  $\rho_w$  (Figure 4a), but distinct site-specific relationships appeared to exist with species occurring at the wetter forest site having greater values of sapwood  $C$  at a given value of  $\rho_w$  ( $F = 40.6$ ,  $P = 0.0004$ ). Maximum values of  $C$  were similar ( $\sim 400 \text{ kg m}^{-3} \text{ MPa}^{-1}$ ) at both sites. Bulk leaf  $C$  on a mass basis was inversely related to  $\rho_w$  ( $P = 0.004$ ) with species from both sites appearing to share a common relationship (Figure 4b).

The leaf area to sapwood area ratio of upper-canopy branches increased about threefold with a doubling of  $\rho_w$  (Figure 5a). Although a single linear regression fitted to data from both sites was highly significant ( $r^2 = 0.66$ ,  $P = 0.0002$ ), the re-

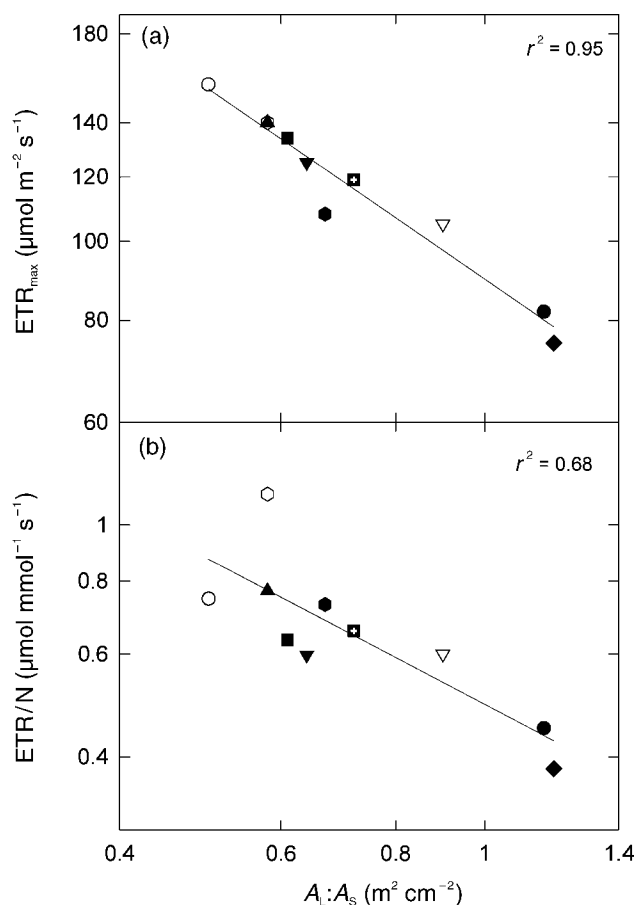

Figure 2. Log-log plots of (a) maximum photosynthetic electron transport rate per unit leaf area ( $ETR_{max}$ ) and (b) maximum electron transport rate per unit leaf nitrogen ( $ETR/N$ ) in relation to the branch leaf area:sapwood area ratio ( $A_L:A_S$ ) for 10 Panamanian forest tree species. relationship for the trees studied at the drier Parque Metropolitano site was much less variable ( $r^2 = 0.97$ ,  $P < 0.0001$ ). Scaling of transpiration on a unit branch sapwood area basis with  $\rho_w$  reduced transpiration by about 20% over the range of  $\rho_w$  observed (Figure 5b). In contrast, scaling photosynthetic capacity ( $ETR_{max}$ ) per branch sapwood area increased photosynthetic capacity by about 30% over the same range of  $\rho_w$  (Figure 5b). The total amount of foliar N per unit sapwood area increased from  $\sim 60$  mmol N cm $^{-2}$  sapwood area in the species with the lowest  $\rho_w$  to  $\sim 210$  mmol N cm $^{-2}$  in the species with the highest  $\rho_w$  ( $P = 0.0004$ , Figure 5c).

Symbols as in Figures 1 and 2.

## Discussion

Simple tree architectural and wood physical properties ( $A_L:A_S$  and  $\rho_w$ ) accounted for a large fraction of the variation in several leaf and stem functional traits among individuals and species growing at contrasting sites. As hypothesized,  $A_L:A_S$  appeared to be a reliable proxy for  $K_i$ , and  $\rho_w$  served as a proxy for  $k_s$ ,  $C$  and their impact on leaf water relations. The scaling relationships found here have practical and theoretical implications for understanding and predicting emergent properties of complex multi-species ecosystems. These relationships obtained from data collected over multiple years on individuals growing in contrasting sites and representing different tree functional groups, are unlikely to be merely correlative, but imply direct or indirect mechanistic links between variables as we argue below.

### Branch architectural constraints on leaf gas exchange

As a relative index of potential transpirational demand in relation to the hydraulic capacity of the xylem,  $A_L:A_S$  is an important component of tree hydraulic architecture. Results of a number of studies suggest that  $k_i$  scales uniformly with  $A_L:A_S$  among co-occurring species with  $A_L:A_S$  explaining 50% or more of the variation in  $k_i$  (Tausend et al. 2000, Bucci et al. 2005). Furthermore, adjustments in  $A_L:A_S$  have been shown to

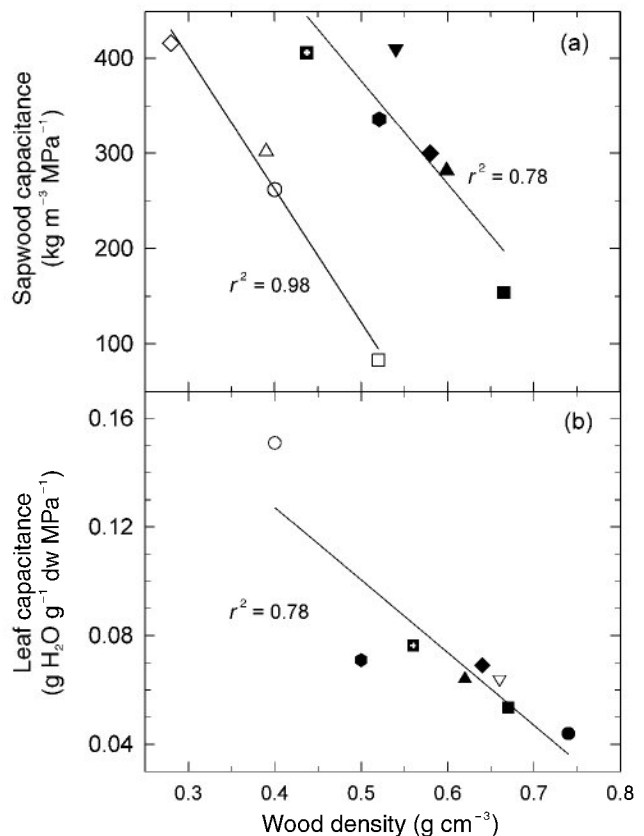

Figure 4. (a) Sapwood and (b) leaf capacitance in relation to wood density for several Panamanian forest tree species. Symbols as in Figures 1 and 2.

play a role in conserving  $k_1$  under a range of circumstances such as exposure to seasonal drought (Bucci et al. 2005) and pathogens that reduce xylem conductivity (Meinzer et al. 2004). The tendency for  $A_L:A_S$  to decrease with increasing tree height (McDowell et al. 2002a) can be interpreted as a compensatory response that maintains  $K_1$  as the length and tortuosity of the hydraulic path increase (McDowell et al. 2002b). Thus,  $A_L:A_S$  may be a reliable surrogate for  $K_1$  despite species-specific differences in sapwood specific conductivity. Because  $K_1$  is a major determinant of the relationship between  $E$  and  $\Psi_L$ , stomatal control of  $E$  is closely coordinated with variation in  $K_1$  (Meinzer and Grantz 1990, Meinzer et al. 1995, Hubbard et al. 2001), and therefore should be coordinated with

$A_L:A_S$ . In agreement with this,  $E$  decreased by 94% as  $A_L:A_S$  increased five-fold from  $\sim 0.3$  to  $1.5 \text{ m}^2 \text{ cm}^{-2}$  (Figure 1). The dependence of  $E$  on  $A_L:A_S$  conformed with an exponential decay function, consistent with the exponential decline in  $k_1$  with increasing  $A_L:A_S$  (Tausend et al. 2000, Bucci et al. 2005). Estimates of  $E$  and  $A_L:A_S$  were not entirely independent in the present study because  $E$  was calculated by multiplying sap flux by branch sapwood area then normalizing by the leaf area distal to the sap flow sensors. Nevertheless, a previous study demonstrated that stomatal conductance scaled uniformly with independently measured  $k_1$  among 20 Panamanian forest tree species (Santiago et al. 2004) and in the present study  $k_1$  was significantly correlated with  $A_L:A_S$  (Table 2) among some of the same species.

Our results suggest that increasing  $A_L:A_S$  imposed a greater relative constraint on  $E$  than on photosynthetic capacity ( $\text{ETR}_{\text{max}}$ ), which declined by about 50% as  $A_L:A_S$  increased from 0.5 to  $1.2 \text{ m}^2 \text{ cm}^{-2}$  (Figure 2a). Over a similar range,  $E$  decreased by nearly 80%. Thus, relative stomatal limitation of photosynthesis, and therefore intrinsic water-use efficiency, should have increased as  $A_L:A_S$  increased. Potentially lower photosynthetic nitrogen-use efficiency in trees with greater  $A_L:A_S$  (Figure 2b) appeared to result largely from coordination of  $\text{ETR}_{\text{max}}$  with increased stomatal constraints on photosynthesis as there was no tendency for leaf N content to be higher in individuals with greater  $A_L:A_S$  (Table 2).

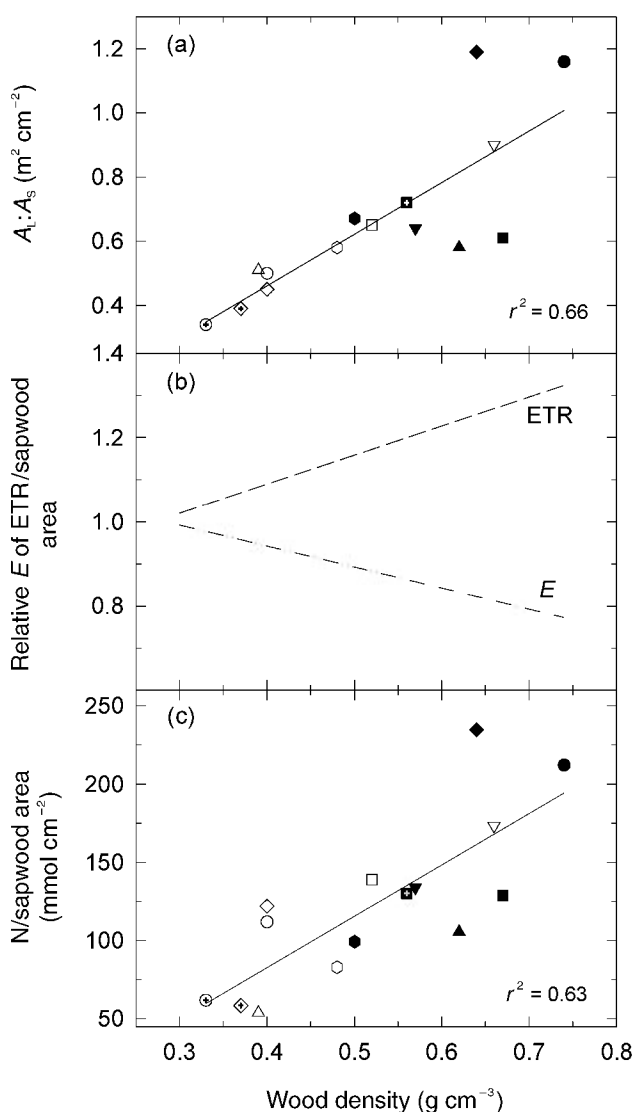

Figure 5. Branch-scale architectural and functional traits in relation to branch wood density for Panamanian forest tree species. (a) Leaf to sapwood area ratio ( $A_L:A_S$ ). (b) Relative trends of maximum transpiration ( $E$ ) and maximum photosynthetic electron transport rate ( $\text{ETR}_{\text{max}}$ ) per unit branch sapwood area. (c) Total leaf N per unit sapwood area. Symbols as in Figures 1 and 2.

#### Wood density as a scalar of functional traits

Coordination between leaf water relations traits and  $\rho_w$  was likely mediated by the inverse relationship between sapwood  $k_s$  and  $\rho_w$  (Figure 3b). The relative xylem lumen volume available for water transport is inversely related to  $\rho_w$  and in diffuse-porous species having a relatively large fraction of vessels close to the hydraulic mean diameter,  $k_s$  should scale predictably with  $\rho_w$  (Stratton et al. 2000, Bucci et al. 2004). However, a trade-off between  $k_s$  and  $\rho_w$  is less likely in ring-porous species with few large vessels and a high density of fibers because  $k_s$  increases with the fourth power of vessel diameter. Leaf-specific conductivity also showed a strong negative correlation with  $\rho_w$  (Figure 3c, Table 2), implying lack of a compensatory decline in  $A_L:A_S$  constraining variation in  $k_1$  with increasing  $\rho_w$ . Rather, the roughly threefold increase in  $A_L:A_S$  with increasing  $\rho_w$  (Figure 5a) did not mitigate but amplified the negative impact of increasing  $\rho_w$  on hydraulic efficiency, causing the relative variation in  $k_1$  to be more than twice as great as that of  $k_s$  as  $\rho_w$  varied between 0.4 and  $0.74 \text{ g cm}^{-3}$  (cf. Figures 3b and 3c).

The positive relationship between  $A_L:A_S$  and  $\rho_w$  found here seems counterintuitive, but is consistent with the findings of Bucci et al. (2004) for six Brazilian savanna species and Wright et al. (2006) for species representing three Australian vegetation types. In contrast, negative associations between  $A_L:A_S$  and  $\rho_w$  have been reported for chaparral shrubs (Ackerly 2004) and several Floridian oak species (Cavender-Bares et al. 2004). The specific selective pressures responsible for these opposing scaling relationships have not been identified. In the

present study, the potential gain in photosynthetic capacity on a branch sapwood area basis associated with increasing  $\rho_w$  (Figure 5b) may have offset the negative impact of higher  $\rho_w$  on branch hydraulics (Figure 3b) and leaf water status (Figure 3a). The coexistence of species representing a broad range of  $\rho_w$  and  $A_L:A_S$  at the Parque Natural Metropolitan site (Figure 5a) suggests that in this early successional secondary forest, a particular combination of  $A_L:A_S$  and  $\rho_w$  may have neutral consequences for competitive ability. The prevalence of species with higher  $A_L:A_S$  and  $\rho_w$  at Parque San Lorenzo (Figure 5a) implies that this combination of branch architecture and mechanical strength may confer a competitive advantage in a mature forest.

The hydraulic consequences of variation in  $\rho_w$  were evident in the relatively large range in daily minimum  $\Psi_L$  from  $-1.4$  MPa in *Ficus insipida* to  $-2.5$  MPa in *Aspidosperma cruenta* (Figure 3a). The decline in  $\Psi_L$  with increasing  $\rho_w$  implies that stomatal coordination of  $E$  with  $k_i$  yielded a curvilinear relationship consistent with anisohydric regulation of minimum  $\Psi_L$  across species even though individual species may display isohydric behavior (Hubbard et al. 2001, Bucci et al. 2005, Fisher et al. 2006). Variation in  $\Psi_{\pi z}$  with  $\rho_w$  paralleled that of minimum  $\Psi_L$ , suggesting that minimum turgor remained nearly constant at 0.7 to 0.8 MPa as  $\rho_w$  varied across species. Nevertheless, the positive correlation between LMA and  $\rho_w$  (Table 2) is suggestive of greater relative constraints on leaf expansion in species with denser wood. Scaling of  $\Psi_L$  and  $\Psi_{\pi z}$  with  $\rho_w$  is consistent with earlier findings of strong constraints imposed by  $\rho_w$  on leaf water relations (Meinzer 2003, Bucci et al. 2004, Gartner and Meinzer 2005).

Inverse relationships between  $\rho_w$  and stem and leaf  $C$  (Figure 4) suggested additional hydraulic costs of increasing  $\rho_w$ . Given the role of capacitance in buffering diurnal variation in stem and leaf  $\Psi$  (Meinzer et al. 2003, 2008, Scholz et al. 2007), increasing  $\rho_w$  implies further stomatal restriction of  $E$  beyond that associated with reduced  $k_s$  to constrain variation in  $\Psi$ . The basis for the consistent difference in the relationship between sapwood  $C$  and  $\rho_w$  among individuals growing at the two sites (Figure 4a) was not determined. Depending on the relative contributions of the compartments from which water is withdrawn, the dependence of sapwood volumetric  $C$  on  $\rho_w$  may be determined largely by the osmotic and elastic properties of xylem parenchyma and by xylem vulnerability to embolism (Scholz et al. 2007, Meinzer et al. 2008).

#### Leaf versus branch level properties

Trends in a suite of tree functional and architectural traits appeared to be inextricably linked via the hydraulic and mechanical consequences of variation in  $\rho_w$ . The impact on  $k_i$  of the sharp decline in  $k_s$  with increasing  $\rho_w$  was amplified by a concurrent increase in  $A_L:A_S$ . Consequently, coordination of gas exchange with  $k_i$  led to sharp declines in leaf-level  $E$  and photosynthetic capacity with increasing  $A_L:A_S$ . Despite stomatal coordination of  $E$  with  $k_i$ ,  $\Psi_L$  declined in a linear fashion with increasing  $\rho_w$ , which required increased allocation to osmotically active solutes to maintain turgor (Figure 3a) and likely contributed to increased leaf mass per area (Table 2).

However, the apparent consequences of higher  $\rho_w$  may depend on the scale at which functional traits are characterized. The negative hydraulic impacts of increasing  $\rho_w$  may have been partly offset by an associated increase in branch mechanical strength (van Gelder et al. 2006), permitting the display of a greater leaf area per branch cross-sectional area ( $A_L:A_S$ ). At the branch level, the relative increases in  $A_L:A_S$  and allocation of N with increasing  $\rho_w$  were similar because leaf-level N content did not vary significantly with increasing  $A_L:A_S$  or  $\rho_w$  (Table 2). These parallel changes in  $A_L:A_S$  and N allocation were associated with a projected 30% increase in  $ETR_{max}$  on a branch sapwood area basis as  $\rho_w$  doubled (Figure 5b). Nevertheless, the compensatory adjustments in tree architecture and N allocation at the branch level were insufficient to completely offset the increased carbon and hydraulic costs of producing denser wood, consistent with slower growth rates of tropical trees with dense wood (Suzuki 1999, Muller-Landau 2004).

#### Acknowledgments

This research was supported by National Science Foundation Grant IBN 99-05012 to F. Meinzer and G. Goldstein. We thank the Smithsonian Tropical Research Institute for providing facilities and logistical support, and the expertise of the canopy crane operators.
