

Low beta diversity of herbivorous insects in tropical forests

Vojtech Novotny, Scott E. Miller, Jiri Hulcr, Richard A. I. Drew, Yves Basset, Milan Janda, Gregory P. Setliff, Karolyn Darrow, Alan J. A. Stewart, John Auga, Brus Isua, Kenneth Molem, Markus Manumbor, Elvis Tamtai, Martin Mogia & George D. Weiblen

Supplementary Material

Supplementary Results

Species distribution and host specificity

The maximum possible geographic span for a particular herbivore species is a function of the combined distributions of all recorded hosts. It amounted to the entire 513 km span for all 76 Lepidoptera species analyzed. However, not all host species were sampled at all eight sites even when present, so the maximum geographic span we could observe for different Lepidoptera species ranged from 352 to 513 km (Supplementary Appendix S2). This maximum distribution was reached by 50 out of 76 Lepidoptera species while the remaining 26 species occupied 31 – 97% (median 88%) of the geographic span permitted by the distribution of their host plants.

Supplementary Figures

Fig. S1. The probability $C(d)$ that caterpillars are conspecific when randomly selected from the same host plant species at study sites separated by the distance d as a function of distance. Mean (\pm S.E.) values were calculated for caterpillar communities from 5–12 plant species sampled simultaneously at each pair of study sites. $C(d)$ was not a function of distance (Pearson r , $P > 0.2$). The intrasite $C(d)$ where $d = 0$ –5 km is shown but was not included in the correlation.

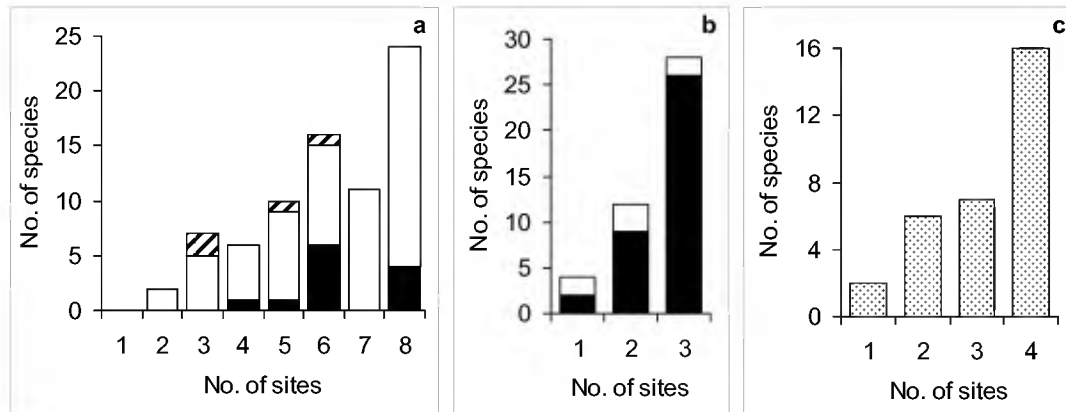

Fig. S2. Geographic distribution of caterpillar (a), ambrosia beetle (b) and fruit fly (c) species in New Guinea lowland rain forests. Geographic distribution was quantified as the number of sites occupied from eight sites sampled for caterpillars, three sites for ambrosia beetles and four sites for fruit flies. Only caterpillar species with ≥ 23 , ambrosia beetle species with ≥ 8 and fruit flies with ≥ 11 reared individuals were included (see Supplementary Methods for the justification of these abundance thresholds). Species were classified as generalists, feeding on >1 study genus (black), clade specialists, feeding on >1 species from a single genus (white), and monophages, feeding on a single plant species (hatched). The host range of fruit flies (stippled) was not known as they were not reared from their hosts. Note that monophages could be recognised only in the caterpillars as the ambrosia beetles were not sampled from multiple congeneric tree species. Host specificity was not correlated with geographic distribution (caterpillars: Spearman r , $P > 0.05$, ambrosia beetles: Mann-Whitney test, $P > 0.05$). The herbivore species are listed in Supplementary Appendices S2 – S4.

Fig. S3. Relationship between the geographic distribution of plant species and the average geographic distribution of their caterpillar species. The plant and herbivore distribution was measured as the distance between the two most distant occurrences of the species (in km); the average value was calculated for all caterpillar species sufficiently abundant to be analysed and feeding on each plant species. There was no relationship between the range size of the plant species and the range sizes of their herbivore species (Spearman r , $P > 0.4$).

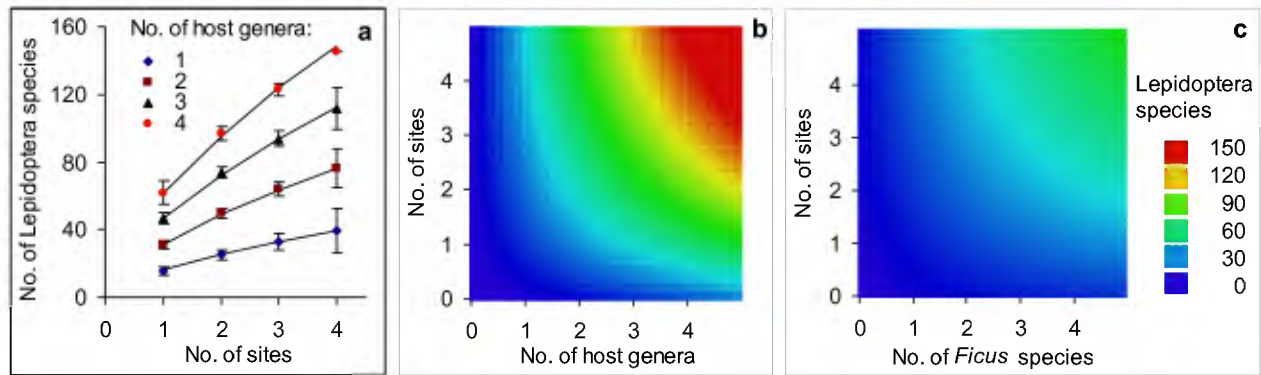

Fig. S4. Accumulation of Lepidoptera species with plant species and area. The number of Lepidoptera species (S) feeding on all possible combinations of 1–4 host species sampled at 1–4 sites was predicted as $\log S = 1.208 [\pm 0.004] + 0.964 [\pm 0.006] \log(\text{host genera}) + 0.637 [\pm 0.006] \log(\text{sites})$ for host species from four genera and $\log S = 1.023 [\pm 0.003] + 0.715 [\pm 0.007] \log(\text{host species}) + 0.568 [\pm 0.007] \log(\text{sites})$ for *Ficus* species ($R^2 > 0.99$ and $N = 16$ for both models, S. E. for each parameter is in parentheses, interaction between the two independent variables was not significant). Supplementary Table S2 lists the plant species and localities used in the analysis. Model predictions (solid lines) for hosts from different genera and the mean observed values (markers with S.E. bars) are shown in (a), expected herbivore richness for different host genera in (b) and expected herbivore richness for different *Ficus* species in (c). Note that herbivore species accumulated more rapidly with the addition of hosts than with the addition of sites.

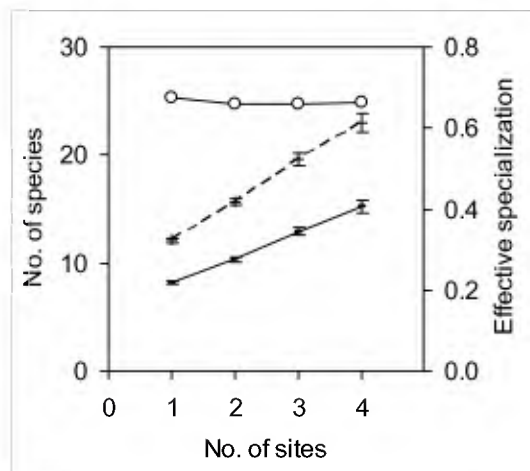

Fig. S5. The effect of geographic scale on the effective specialization and species richness of Lepidoptera feeding on *Ficus* trees. The effective specialization (circles), the number of species per host plant species (dashed line), and the number of unique species per host plant species (solid line) were estimated for Lepidoptera feeding on four species of *Ficus* sampled at 1–4 sites (see Table S2 for the list of plant species and sites). The mean (\pm S. E.) values of species richness were calculated from four *Ficus* species studied. The values for 2 and 3 sites were estimated as means from all possible combinations of sites from the four studied. The effective specialization, i.e. the proportion of herbivorous species feeding on a particular host plant that is unique to that plant, was estimated as the ratio of the total number of herbivorous species found on all four hosts studied, divided by the number of host-plant records involving these hosts²⁴. The number of herbivore species unique for a particular plant species is a product of the effective specialization and the number of species recorded on this plant species.

Supplementary Tables

Table S1. Community similarity and geographic distance for plants and Lepidoptera in New Guinea lowland rain forest. The relationship between community similarity and geographic distance was tested for (i) species in four plant genera and (ii) Lepidoptera species feeding on conspecific hosts at eight study sites. Similarity (Sørensen index I_s for plants and Chao-Sørensen index I_c for Lepidoptera) as a linear, exponential, power or logarithmic function of distance d was tested by the Mantel procedure. The explained variance (r^2) is given for the best fitting function when significant ($P < 0.05$). Only plant species sampled at $s > 3$ surveys were included in the analysis of caterpillar community similarity.

	r^2	Similarity function	s
Plant genus:			
<i>Ficus</i>	N. S.		8
<i>Macaranga</i>	0.13	$I_s = 0.603 - 0.0004 d$	8

Table S3. Species richness (S) and basal area (BA) of four plant genera at eight lowland rain forests in New Guinea. Species richness was based on qualitative floristic surveys of approximately 25 km² of primary and secondary forests at each site. BA was estimated by enumeration of all plants >1.5m high in 50 plots, 400 m² each, equally distributed between primary and secondary forest vegetation at each site. All parameters are given as means \pm S. E. Abbreviations: S_{total} = the total number of species across all sites; S_{local} = the average number of species per site; $\%S_{sampled}$ = the percentage of local congeners sampled for herbivores; BA_{local} = the average combined basal area (in cm²/ha) of all congeners per site; $\%BA_{sampledG}$ = the average percentage of basal area per site represented by species sampled for herbivores out of local congeners; $\%BA_{sampledT}$ = the average percentage of basal area per site represented by species sampled for herbivores out of the woody vegetation.

Genus	S_{total}	S_{local}	$\%S_{sampled}$	BA_{local}	$\%BA_{sampledG}$	$\%BA_{sampledT}$
<i>Ficus</i>	87	43.1 \pm 2.17	11 \pm 0.9	14600 \pm 5073	40 \pm 10.4	1.7 \pm 0.68

Supplementary Appendices

Appendix S1. Species composition of *Ficus*, *Macaranga*, *Psychotria* and *Syzygium* at eight study sites in Papua New Guinea. The study site names (Fig. 1) are abbreviated to their first three letters. The number of sites where the species occurred (n) and the longest distance between two occurrences in km (D) is reported. Voucher specimens are deposited at the University of Minnesota Herbarium (MIN) and Lae Herbarium (LAE).

Appendix S2. Geographic distribution of Lepidoptera in the New Guinea lowland rain forest study area. N = the number of individuals reared from eight study sites (only species with $N \geq 23$ included; see Supplementary Methods); n = the number of sites where a species was recorded; G = predicted geographic distribution, based on occurrence of known hosts sampled for herbivores; D = observed geographic distribution (the longest distance between two occurrences, in km). Morphotype codes are reported for unidentified species. Insect vouchers are deposited at the Smithsonian Institution, Washington, DC, and the National Agriculture Research Institute in Port Moresby.
