CHAPTER 8
NITROGEN FIXING ACTIVITY ASSOCIATED WITH
SUBTIDAL MACROPHYTES OF THE
SEYCHELLES ISLANDS

BY
V.S. Odintsov*

INTRODUCTION

The ability of microorganisms to fix dinitrogen has significance for the functioning of marine
offshore ecosystems in oligotrophic oceanic regions. The most effective utilization of fixed nitrogen
occurs in associations of nitrogen-fixing microorganisms with macrophytes where direct contact is
present. There are many examples (e.g., Harlin and Craigie 1975, Wetzel and Penhale 1979) of
intensive exchange of nitrogen, phosphorus and carbon between epiphytes and their host
macrophytes. It is known (Jones and Stewart 1969) that macrophytes consume fixed nitrogen
released by nitrogen-fixing epiphytes. In some macrophyte communities, the correlation between
productivity and epiphytic nitrogen fixation has been shown (Capone et al. 1979). Epiphytic
nitrogen fixing activity associated with brown algae such as Sargassum may be so high that 40% of
the nitrogen requirements of the algae can be met by such nitrogen fixation, assuming that all of the
fixed nitrogen is consumed (Carpenter 1972, Hanson 1977, Odintsov and Lapteva 1984, Odintsov
1988).

The objective of this work was to determine the significance of nitrogen-fixing epiphytes on
subtidal seagrasses and seaweeds of the Seychelles Islands in regard to their role in providing island
ecosystems with nitrogen nutrients.

METHODS AND MATERIALS

Abundant macrophytes such as Thalassodendron ciliatum, Sargassum cristaefolium, Sargassum
microcystum, Halimeda gracilis, as well as the more uncommon algae Caulerpa brachypus, Padina sp.,
Turbinaria ornata and Lobophora variegata, were used in the experiments. Nitrogen fixing activity of
epiphytes was determined by the acetylene reduction method (Stewart et al. 1967), except the
samples were incubated without a gas phase and sampling for gas chromatography was done with
evacuated vials (Odintsov 1981). The samples were incubated in natural light. During one
experiment, half of the Sargassum samples were washed to remove epiphytes and determine the
nitrogen fixation role of symbionts living inside the thalli, the other half were used to compare the
levels of the more common epiphytic nitrogen fixation. Following the experiments, portions of the
samples incubated were fixed for electron microscopic study.

RESULTS AND DISCUSSION

The levels of nitrogen fixing activities associated with Seychelles subtidal macrophytes are presented in Table 1. Negligible nitrogen fixation was detected in the samples of *Thalassodendron ciliatum* and *Lobophora variegata* collected near Desroches Island, as well as in samples of *T. ciliatum* from Coetivy Island (depth 26 m) and in samples of *Turbinaria ornata* incubated in the dark. Great differences in nitrogen fixation rates were observed in all other samples. The greatest activity was shown in specimens of *Sagassum cristaeforme* from Praslin Island and *Padina* sp., which was approximately the same as that shown by *Thalassia testudinum* and *Zostera marina* populations from temperate waters (Capone and Taylor 1979, Odintsov and Lapteva 1984). The rate of nitrogen fixation of the seagrass *T. ciliatum* was higher than that of pelagic *Sargassum* (Carpenter 1972, Hanson 1979) but lower than the rates recorded for temperate seagrasses. Therefore, populations of *T. ciliatum* do not appear to serve as an important nitrogen nutrient source for surrounding areas. Conversely, communities of *S. cristaeforme* with high biomass (Table 1) can show considerable N-fixation, similar to that of *Sargassum ilicifolium, S. polycistum* and *S. feldmannii* from the Thou Island area in the South China Sea (Odintsov 1988). Nitrogen fixing activity in a *Sargassum microcystum* community was comparable to that of temperate seagrasses having smaller biomass. Epiphytic nitrogen fixation in *Padina* sp. was high, but probably is important only for the host plant, because *Padina* sp. does not form communities. The same can be said concerning nitrogen fixation associated with *Turbinaria ornata, Halimeda gracilis* and *Caulerpa brachypus*.

Statistically significant decreases of nitrogen fixing activity in the dark was noted only in *Sargassum cristaeforme* from Praslin Island and *Padina* sp., in which photosynthetic nitrogen fixing epiphytes appear to be predominant. Nitrogen fixing epiphytes of *S. cristaeforme* are present in lightly washed mucous extracts and are not firmly attached to thalli. The exact location of such epiphytes awaits further electron microscopy study. It may be concluded that only *Sargassum* communities serve as important sources of nitrogen nutrients for surrounding ecosystems.
